My multi master Model

I believe it would benefit the company if we switch to a multi master model. I know it will be difficult to sync them but we have an amazing developer team who can definitely do it. The multi master model will help our company provide our services for our customers for longer and cheaper because a multi master system is very affordable compared to scaling our single database. We can also provide our service more consistently because if one of our servers goes down we can fix it and our users can use another of our master systems. Also with our multi master databases we can place these servers closer to our country wide customers to reduce latency with transfer speeds. There are many reasons to switch to a multi master system but I will deep dive into these three.

On my first point about scalability, the single master system is very expensive to expand and if we expand now we will need to expand more later. The multi master system is very cost efficient to expand. Our single database is already using almost all the ports in our server, to expand our single database we will need expensive servers to handle the extra hard drives but if we get a multi master system it can use basic servers and save the company lots of money. Also if we can't afford the expensive servers they are available for long term lease but this involves a long term contract that we do not want. The best part about expanding to two or three master databases is we can always add more if we need to, we can expand from one to 100 for more returns every expansion. As you can see the multi master system is very scalable as is our company and they can scale together.

On my second point of consistency, do you remember when our server went down in may of 2008, none of our customers could read or write to our database for hours. This wouldn't be a problem on a multi master system because even if the local server went down in someone's area we could connect them to another server without the knowledge of the customer. Speaking of local servers we could put servers in different locations near our large consumer hubs and that would reduce wait times for our users. Also if one or more of our servers goes down we can keep all the entry data and recover off of another master system. So having a multi master system can help with downtime and data recovery.

My third and final point I will be discussing today is the speed for our users. I have already discussed the fact that we could place our servers around the globe to speed up the transfer for our customers but the multi master model speeds our product up for our users in other ways. One of these other ways is the multi-write option we have with multiple masters, we can have different people write at the same time instead of having them queue up in a cash. If one of our bigger customers needs to write a lot quickly we can spread them out to multiple servers and not overstress their local node.

In conclusion we should add servers to make our company run a multi-aster model instead of our single database. This change would save the company money that might be split between us and get us all making more money. This change would also be more easily scalable in the future. This change would keep consistency and diminish the devastation of a crash. It would keep the users being able to write to another node and can keep the crash data like a same level back-up. This new system could increase the speed for users, not only in the connection speed, but also in the parallel write capabilities. These are few of the many reasons to switch to a multi master model, another reason is because of the alliteration of "multi master model".
